Abstract. Aortic valve (AoV) stenosis is the third most common cardiovascular disease. The pathogenesis of AoV stenosis is associated with an inflammatory process where MMPs serve important roles. The aim of the present study was to determine the association between matrix metalloproteinases (MMPs), tissue inhibitors of metalloproteinases (TIMPs) and inflammatory factors, and AoV stenosis at various degrees of severity compared with the control. A total of 18 patients with mild, 19 with moderate and 15 with severe AoV stenosis were included in the present study, and 50 individuals were enrolled in the control group. The severity of stenosis was determined by echocardiography. The expression levels of chemerin, fibroblast growth factor 21, MMP-1, -3, and -9, and TIMP-1 and -3 were analyzed by ELISA. Data were analyzed using GraphPad Prism7 software. The expression levels of MMP-1 was increased in patients with stenosis compared with the control group (P=0.0043). Distribution of the trimodal MMP-1 values was obtained in the stenosis group and monomodal in the control group. A total of 80% of patients in the stenosis group presented significantly increased

expression levels of MMP-1 compared with the control group (P=0.0002). Expression of MMP-1 was significantly higher in all stenosis groups compared with the control. The highest expression level of MMP-1 appeared in patients with moderate stenosis (P<0.0001). There was no significant difference in the expression of MMP-3, MMP-9 and TIMP-1 in the aortic stenosis group, compared with the control group. A positive correlation between MMP-1 and MMP-9 expression levels was identified (r=0.37; P=0.017). The increase of MMP-1 was correlated with the increase of MMP-9, but not with the level of MMP-3. The expression levels of chemerin was significantly elevated in patients with stenosis compared with healthy patients. The highest expression levels of chemerin were determined in patients with mild (P=0.0001) and moderate (P=0.0007) stenosis and decreased with the grade of severity compared with the control group. The expression of FGF-21 was significantly different between the control and mild (P=0.013), moderate (P=0.015) and severe stenosis (P=0.003) groups. The expression levels of FGF-21 increased with the increase in severity grade, reaching the maximum for severe stenosis. The results of the present study indicated that the inflammatory process is predominantly occurring at the early, mild stage of stenosis and the most prominent extracellular matrix remodeling occurs in moderate stenosis (demonstrated by MMP-1 levels). In patients with severe stenosis, the levels of MMP-1 and chemerin (which are lower than in a case of mild or moderate stenosis) could indicate the development of calcinosis and the reduction in activity or inactivation of the inflammatory process.

Introduction

Acquired calcific aortic valve (AoV) stenosis is the most common valvular disease in the USA and Europe and is the second most frequent cause for cardiac surgery (1). The prevalence of aortic valve stenosis is 0.2% among adults aged 50-59 years, 1.3% among patients aged 60-69 years, and ≤9.8% among patients aged 80-89 years (2).

Overall, AoV stenosis is present in 2.6% of adults >75 years of age (3). The average time from diagnosis of aortic sclerosis to the development of moderate and severe AoV stenosis is 6 and 8 years, respectively (4).

Among symptomatic patients with medically treated moderate-to-severe aortic stenosis, mortality from the onset of symptoms is ~25% at 1 year and 50% at 2 years (5). Symptoms of aortic stenosis usually develop gradually after an asymptomatic latent period of 10-20 years (6).

AoV stenosis has been previously considered to be the cause of aging and atherosclerosis; however, in recent years this view has changed. At present, AoV stenosis is considered to be an active process. Inflammatory factors, extracellular matrix remodeling and calcification processes serve important roles in the pathogenesis of AoV stenosis (7).

Calcific AoV stenosis is characterized by cell proliferation and development of remodeling processes in the extracellular matrix. Matrix metalloproteinases (MMPs) serve important roles in the remodeling processes, which leads to the degradation of the extracellular matrix (8-10).

MMPs are some of the most frequently studied extracellular matrix proteins in the pathogenesis of calcific AoV stenosis (11). MMPs are zinc-dependent endopeptidases (collagenases, gelatinases and stromelysins) that serve roles in both physiological and pathological remodeling of the extracellular matrix in a number of tissues and diseases (12). Tissue remodeling is affected by the local balance between MMPs and endogenous tissue inhibitors of metalloproteinases (TIMPs) (13,14). The present study determined the expression levels of MMP-1, -3 and -9 in the blood serum and the corresponding TIMP-1 and -3 expression. These MMPs, in particular MMP-1 and MMP-9, have been described by numerous researchers who have investigated their possible association with stenosis (12,13,15,16). However, mainly as a material using tissues, removed during the aortic valve replacement surgery, consequently, these studies cannot compare the changes between severity degrees of aortic valve stenosis. The number of histological materials included in these previous studies was frequently small and there were ethical restrictions associated with the establishment of appropriate control groups.

The current study aimed to clarify the factors that serve an active role in the development of AoV stenosis, and to determine their presence and significance by determining their serum levels in patients with aortic valve stenosis of different severity degrees in comparison with the control group. This method was used to estimate the sequence of processes occurring during the development of aortic valve stenosis.

C-reactive protein is known as a stable inflammatory factor and a marker of inflammation, and chemerin is a relatively new biomarker involved in various inflammatory processes. Chemerin has been previously demonstrated to be released by fibroblasts in the heart (17). FGF-21, that has been described as a factor with a broad spectrum of manifestations, may serve a cardioprotective role, and may contribute to the development of fibrosis and may be excreted by cardiac cells (18-21).

The aim of the present study was to demonstrate the involvement of inflammatory factors and MMPs in the development of aortic valve stenosis, their role in progression of the disease according to the AoV stenosis severity grades, and, therefore indirectly provide evidence of the possible sequence and mechanism of the development of AoV stenosis.

Patients and methods

Study population. The current study was conducted from January 2013 until the end of December 2016 at the Vidzeme Regional Hospital (Valmiera, Latvia), P. Stradins Clinical University Hospital (Riga, Latvia) and at the polyclinic-Zemgale Health Centre (Jelgava, Latvia). The study protocol was approved by the Riga Stradins University Ethics Committee on Research on Humans and the study protocol conforms to the Ethical Guidelines of the 1975 Declaration of Helsinki. A total of 102 patients were selected according to inclusion and exclusion criteria and divided in two core groups, an AoV stenosis group and a control group. The control group included patients without AoV stenosis, aged 55-80 years, which matched the average age of patients with AoV stenosis according to the Guidelines on the Management of Valvular Heart Disease 2012 of the European Society of Cardiology (22). Written informed consent was obtained from each patient enrolled in the current study. Patients were included in the control group according to echocardiographically confirmed results of a healthy aortic valve. Exclusion criteria in both groups included: Obesity, systemic connective tissue diseases, infectious diseases, oncological diseases, diabetes, thyroid dysfunction, moderate, severe and uncontrolled arterial hypertension, with acute coronary syndrome in anamnesis and coronary heart disease, left ventricular systolic dysfunction with reduced ejection fraction below 40%, cerebral infarction, transient ischemic attack, echocardiographically confirmed cardiomyopathy and pathology of other valves. Exclusion criteria in the AoV stenosis group included congenital and rheumatic aortic valve stenosis.

Aortic valve stenosis assessment. All patients were examined echocardiographically and the data were obtained using GE VIVID 7 Dimension Cardiovascular Ultrasound system (GE Healthcare; GE Healthcare, Chicago, IL, USA) and Philips iE 33 Ultrasound Machine (Philips Healthcare, Amsterdam, The Netherlands). Each echocardiography examination was evaluated by 2 professionals. Patients with AoV stenosis were subdivided into three groups depending on the severity grade according to the echocardiography criteria, including aortic jet velocity [Vmax (m/s)], mean pressure gradient [PG (mmHg)], aortic valve area [AVA (cm²)] and indexed AVA (cm²/m²). The following groups were established: i) Severe (Vmax >4 m/sec; PG >40 mmHg; AVA <1.0 cm²; indexed AVA <0.6); ii) moderate (Vmax 3.0-4.0 m/sec; PG 20-40 mmHg; AVA 1.0-1.5 cm²; indexed AVA 0.60-0.85); and iii) mild (Vmax 2.5-2.9 m/sec; PG <20 mmHg; AVA >1.5 cm²; indexed AVA >0.85; Table I).

Biochemical analysis. Venous blood samples were collected and serum was obtained in accordance with the serum preparation instructions (23). Serum samples were stored at -80°C and were available for all 102 patients. The concentration of lipids and C-reactive protein were analyzed via standard methods at the laboratory of the Pauls Stradins Clinical University Hospital (Riga, Latvia). Total cholesterol was determined using the commercially available test [ADVIA® Chemistry Cholesterol_2 (CHOL_2); cat. no. 10376501], Siemens Healthineers, Erlangen, Germany], based on an enzymatic method that utilizes cholesterol esterase and cholesterol

All data are presented as the mean (\pm standard deviation), with the exception of CRP levels presented as the median and interquartile range. All P-values are vs. the control group. BMI, weight in kilograms divided by the square of the height in meters; LDL, low-density lipoprotein cholesterol; CRP is C-reactive protein; SV, stroke volume, measured by left ventricular outflow method; EF, ejection fraction, measured by Simpson's method.

oxidase conversion, followed by a Trinder endpoint (24). The cholesterol esters were hydrolyzed by cholesterol esterase to form cholesterol and free fatty acids. The cholesterol was then converted to cholest-4-en-3-one by cholesterol oxidase in the presence of oxygen to form hydrogen peroxide. A colored complex was then formed from hydrogen peroxide, 4-aminoantipyrine and phenol under the catalytic influence of peroxidase. The absorbance of the complex was measured as an endpoint reaction at 505/694 nm. Triglycerides were determined using commercially the available test [ADVIA[®] Chemistry Triglycerides_2 (TRIG_2) Reagent; cat. no. REF 10335892; Siemens Healthineers], based on the Fossati three-step enzymatic reaction with a Trinder endpoint. The single-reagent procedure quantitates the total triglycerides including the monoglycerides, diglycerides and free glycerol fractions. The triglycerides were converted to glycerol and free fatty acids by lipase. Glycerol was then converted to glycerol-3-phosphate by glycerol kinase, which was further converted with glycerol-3-phosphate-oxidase to form hydrogen peroxide. A colored complex was formed from hydrogen peroxide, 4-aminophenazone and 4-chlorophenol under the catalytic influence of peroxidase. The absorbance of the complex was measured as an endpoint reaction at 505/694 nm. High-density lipoprotein cholesterol and low-density lipoprotein cholesterol were determined using commercially available tests [ADVIA[®] Chemistry Direct HDL Cholesterol (D-HDL) Reagent; cat. no. 07511947 and ADVIA[®] Chemistry LDL Cholesterol

Direct (DLDL) Reagent; cat. no. 09796248 respectively]; Siemens Healthcare Diagnostics Inc., Tarrytown, USA], using the direct method. Direct high-density lipoprotein cholesterol method measured HDL cholesterol in serum without prior separation, based on procedures developed by Izawa *et al* (25). Cholesterol from non-HDL particles was released and eliminated in the first step of the reaction. Cholesterol in HDL particles was further released in the second step by detergent in Reagent 2 [component of the ADVIA[®] Chemistry Direct HDL Cholesterol (D-HDL) kit] and the HDL cholesterol was measured via a Trinder reaction. The low-density lipoprotein cholesterol direct method measured LDL cholesterol in serum. The first step of the reaction eliminated cholesterol associated with lipoproteins other than low-density lipoprotein. A selective surfactant [component of the ADVIA[®] Chemistry LDL Cholesterol Direct (DLDL) kit] released cholesterol preferentially from non-LDL particles. Hydrogen peroxide produced by cholesterol esterase and cholesterol oxidase in the first step was then eliminated by catalase. Another surfactant in Reagent 2 [component of the ADVIA[®] Chemistry LDL Cholesterol Direct (DLDL) kit] released cholesterol from the low density lipoprotein. Azide in R2 inhibited the catalase. Hydrogen peroxide generated by cholesterol esterase and cholesterol oxidase was then quantified using a Trinder endpoint. All methods were performed using the Siemens Advia 1800 analyzer (Siemens Healthcare Diagnostics Inc., Tarrytown, NY, USA) in accordance with the manufacturer's protocol. C-reactive protein was

determined using the particle enhanced turbidimetric method. Human CRP was determined using commercially available test where CRP was agglutinated with latex particles coated with monoclonal anti-CRP antibodies (cat. no. CRPLX; Roche Diagnostics, Basel, Switzerland). The precipitate is determined turbidimetrically at 552 nm. This was performed using the Roche Cobas Integra 400 Plus analyzer (Roche Diagnostics), according to the manufacturer's protocol. Analyses of MMP-1, MMP-3, MMP-9, TIMP-1, TIMP-3, chemerin and FGF-21 were performed at the biochemical laboratory of the Riga Stradins University (Riga, Latvia), using the following ELISA kits: Human MMP-1 (cat. no. EHMMP1; Pierce; Thermo Fisher Scientific, Inc., Waltham, MA, USA); human MMP-3 (cat. no. ELH-MMP3; RayBiotech, Inc., Norcross, GA, USA); human MMP-9 (cat. no. KHC3061; Invitrogen; Thermo Fisher Scientific, Inc.); human TIMP-1 (cat. no. ab100651; Abcam, Cambridge, UK); human TIMP-3 (cat. no. ab119608; Abcam); human Chemerin ELISA (cat. no. EZHCMRN-57K; Merck KGaA, Darmstadt, Germany) and human FGF-21 ELISA (cat. no. EZHFGF21-19K; Merck Millipore, USA). Results were detected using an Infinite 200 PRO multimode reader (Tecan Group, Ltd., Mannedorf, Switzerland) and Multiskan Ascent microplate reader (Thermo Labsystems, Helsinki, Finland). The procedure was performed in accordance with the ELISA kit manufacturer's protocol.

Statistical analysis. All the graphs, calculations, and statistical analyses were performed using GraphPad Prism software version 7.0 for Mac (GraphPad Software, Inc., La Jolla, CA, USA). Comparison of means between different groups was performed using one-way analysis of variance (ANOVA). Brown-Forsythe and Bartlett's tests were applied to determine whether the obtained data were normally distributed. In the case of unequal standard deviations, comparisons of medians between different groups were performed with non-parametric one-way ANOVA on ranks or Kruskal-Wallis test followed by post-hoc analysis. In all cases two-stage step-up method of Benjamin, Krieger and Yekutieli was used as post-hoc analysis (26). Baseline statistics are presented in Table I. All results for age, body mass index, low-density lipoprotein cholesterol, total cholesterol, triglycerides and ejection fraction (measured by Simpson's method), stroke volume (measured by left ventricular outflow method) (27) are presented as the mean \pm standard deviation. Results for high-sensitivity C-reactive protein are presented as the median and interquartile range. As the distribution of data was logarithmic, the geometric mean and geometric standard deviation of the data were used to represent the results. A two-tailed $P < 0.05$ was considered to indicate a statistically significant difference. The correlation analysis method was used to study the associations between quantitative variables. Depending on the data distribution, parametric (Pearson's) or non-parametric (Spearman's) correlation analyses were performed and corresponding characteristics (r_p or r_s) were used.

Results

Patient characteristics. Patient characteristics are presented in Table I. A total of 102 patients were included and divided into three AoV stenosis severity groups and a control group. A total

of 18 patients presented mild, 19 moderate, and 15 severe AoV stenosis, and there were 50 patients without AoV stenosis in the control group. The aforementioned exclusion criteria allowed the selection of appropriate study groups. Although the number of patients in the subgroups was limited, the statistical analysis revealed significant P -values in the range $P < 0.05$ - 0.0001 .

The average age of patients in all of the aortic stenosis groups and the control group were similar, and the mean level of body mass index did not differ between the groups. Triglyceride and low-density lipoprotein cholesterol mean values did not differ significantly between the stenosis groups and the control group. The aortic stenosis patient groups were similar in respect to the mean values of ejection fraction, measured by Simpson's method and stroke volume, measured by left ventricular outflow method. However, ejection fraction in severe aortic stenosis group was significantly decreased ($P = 0.007$) in comparison with the control group. The expression of C-reactive protein was statistically significantly higher ($P = 0.016$) among patients with mild stenosis compared with the control patients (Fig. 1).

Differences in chemerin expression levels between the patient groups. The mean chemerin expression level among all patients with AoV stenosis differed significantly ($P < 0.0001$) compared with the control group (Fig. 2). A more detailed analysis of AoV stenosis subgroups, including mild, moderate and severe (Fig. 3), demonstrated that chemerin level was significantly elevated in all three AoV stenosis groups compared with the control patients and the most pronounced effect was observed in the mild AoV stenosis group ($P = 0.0001$).

Chemerin level in the mild AoV stenosis group was also significantly higher compared with the severe AoV stenosis group ($P < 0.05$), while no significant difference between moderate and severe AoV stenosis groups was observed. Elevated chemerin levels decreased with the increase of AoV stenosis severity, reaching the lowest level in patients with severe aortic stenosis (Fig. 3). This effect was confirmed by regression analysis, where a linear regression line with a negative slope was determined (Fig. 4).

Differences in FGF-21 expression levels between the patient groups. The serum expression levels of FGF-21 were significantly higher among patients AoV stenosis compared with the control group ($P < 0.0001$; Fig. 5). The most significant difference was observed in the severe stenosis group ($P = 0.003$); however, significant differences were also observed in patients with moderate ($P = 0.015$) and mild ($P = 0.013$) stenosis groups compared with the control group (Fig. 6). The increase of FGF-21 serum level (depending on the degree of AoV stenosis), in difference to chemerin, gradually increased, exhibiting a linear tendency, which is presented in Fig. 7 as positive slope of regression. A positive association was observed between the expression of chemerin and FGF-21 in the control group ($r_p = 0.34$; $P = 0.019$), and the aortic valve stenosis group ($r_p = 0.35$; $P = 0.012$) (Fig. 8A and B). An increase in the chemerin level was associated with an increase in FGF-21 concentration. A positive correlation between chemerin expression and serum levels of MMP-9 was also detected (Fig. 8C; $r_p = 0.362$; $P = 0.008$); however, no association between chemerin and high-density lipoproteins (HDL) was identified.

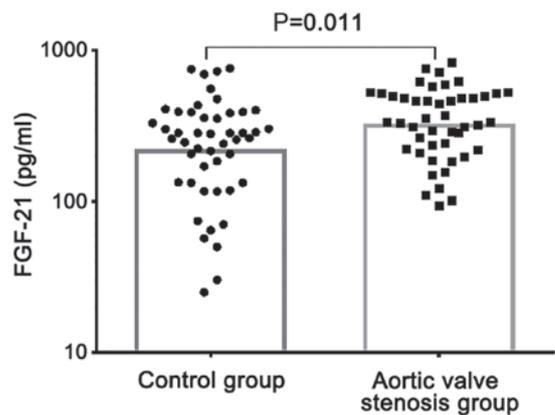

Figure 5. Serum FGF-21 level in the control and AoV stenosis group.

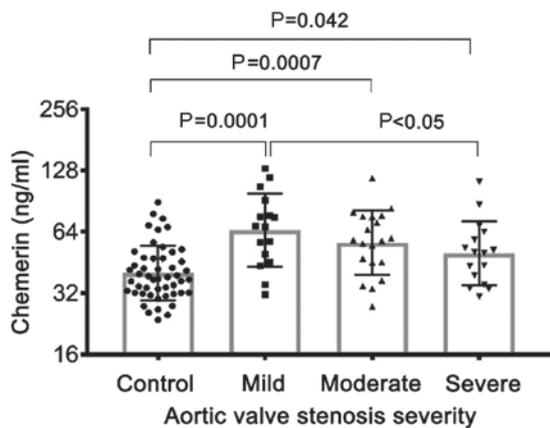

Figure 3. Serum Chemerin level in the control group and in AoV stenosis groups with different grades of severity.

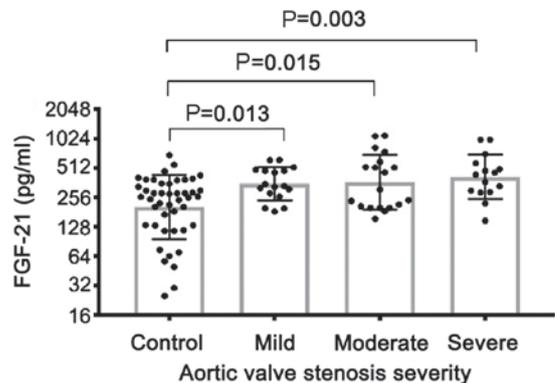

Figure 6. Serum FGF-21 expression level in the control group and in aortic valve stenosis groups with different grades of severity. FGF-21, fibroblast growth factor-21.

Differences in the serum levels of MMPs in patients with different degrees of aortic valve stenosis. The expression of MMP-1 was also significantly increased in patients with AoV stenosis compared with the control group ($P=0.0043$). However, the results and their distribution were different from those obtained with chemerin and FGF-21. It was also demonstrated that patients with aortic valve stenosis exhibited a dual distribution of the response (Fig. 9A). Therefore, the values of MMP-1

were divided into two groups (including control subjects). In order to determine more precisely the differences between the control and stenosis groups, distribution analysis was performed (Fig. 9B) and it was demonstrated that the distribution of MMP-1 was trimodal in the aortic stenosis group and monomodal in the control group. A total of 80% of patients in the aortic stenosis group (marked with a green oval) exhibited a significantly increased MMP-1 expression level compared with the control group ($P=0.0001$; Fig. 9C); however, MMP-1

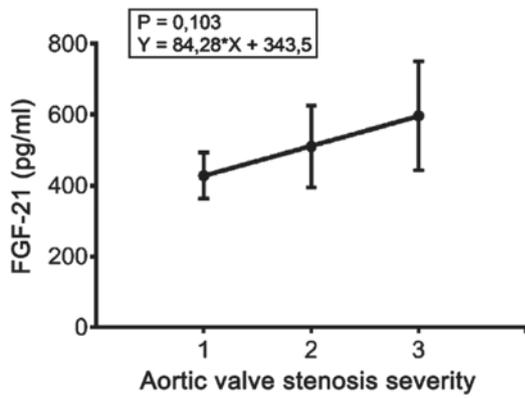

Figure 7. Regression line of the serum FGF-21 level and the aortic valve stenosis severity grade. FGF-21, fibroblast growth factor-21.

expression levels remained unaltered for 20% of patients with aortic stenosis results compared with the control group. The highest MMP-1 expression level was observed in the moderate AoV stenosis group ($P < 0.0001$) and the lowest level in the severe aortic stenosis group ($P = 0.012$), compared with the control patients (Fig. 9D). Analyses of serum expression levels of MMP-3, MMP-9, TIMP-1 and TIMP-3 between patients with aortic valve stenosis and the control patients, did not reveal any statistically significant differences (Fig. 10). A positive correlation was identified between MMP-1 and MMP-9 expression levels ($r_p = 0.37$; $P = 0.017$; Fig. 11A); however, no associations were revealed between the expression levels of MMP-1 and MMP-3 and TIMP-1 (Fig. 11B and C).

Discussion

The present study analyzed the role of MMP-1 in the development of acquired calcific AoV stenosis, and identified the highest serum MMP-1 level in the moderate AoV stenosis group. The results of previous studies investigating the association between MMP-1 an AoV stenosis, the results demonstrated increased MMP-1 levels in damaged aortic valves resulting in degradation of the extracellular matrix components, including interstitial collagen types I, II and III, destruction of collagen, osteoblast differentiation and calcification (7,15,28).

Solache-Berrocgal *et al* (28) studied the association between the MMP-1 1G>2G polymorphism and parameters indicative of mineralization in aortic valves from valve replacement. The results obtained by Solache-Berrocgal *et al* confirmed the association between the highest amounts of calcium in valves with individuals carrying the allele resulting in increased transcription and translation of MMP-1. The association between 1G>2G MMP-1 polymorphism and calcium content of the aortic valve suggests that the 1G allele may exhibit a protective effect against calcium deposits.

The current study analyzed the results of serum MMP-1 expression among patients with AoV stenosis divided into two subgroups. In the current study, 20% of patients with AoV stenosis did not exhibit increased serum MMP-1 levels compared with the control group. Further analysis of expression levels among these patients revealed that all patients exhibited mild AoV stenosis. We assume that this stratification of the results into two subgroups (especially in patients of mild and

moderate stenosis), may be required to determine whether AoV stenosis progressed more slowly among these patients. Other factors possibly involved in the pathogenesis of AoV stenosis should be considered. Mohty with co-authors (29) demonstrated that increased valvular oxLDL expression was associated with an increased tissue remodeling score, suggesting that oxLDL could be involved in the fibrocalcification of the aortic valve. The results of the current study and data from previous studies (8,9,12,13,15,28) lead to a hypothesis that the most pronounced extracellular matrix remodeling occurs among patients with moderate AoV stenosis as the serum level of MMP-1 increases starting from the mild stenosis grade, reaches the maximum level in patients with moderate AoV stenosis, and decreases slightly in patients with severe AoV stenosis. Alterations in serum levels of MMP-1 observed in the present study in patients with different AoV stenosis severity grades

correspond with the results of other studies (9,28) obtained using tissues and histological analyses. The lowest levels of MMP-1 were observed among patients with severe AoV stenosis, which may indicate low or absent inflammation at this stage of the disease and the development of valvular calcinosis.

In the present study, the serum expression level of TIMP-1 did not differ significantly between the control and AoV stenosis groups. Other authors have previously reported similar results. Kaden *et al* (9) studied the association between the inflammation in stenotic valves and the regulation of expression and activation of MMPs. It has been demonstrated that within lesions, leukocytes activated by the secretion of tumor necrosis factor- α , may stimulate valvular myofibroblasts to proliferate and express MMP-1, while TIMP-1 remains unchanged (9). The expression of TIMP-1 was individually variable in both stenotic and control

valves, showing no statistically significant difference between the groups.

The current study did not identify a correlation between the serum levels of TIMP-1 and MMP-1, which meant that TIMP-1 was excluded as a factor that causes an increase of MMP-1. Therefore, the upregulation of MMP-1 may serve as an explanation for the increased concentration of MMP-1 in patients with aortic stenosis, and this increase may be persistent and not regulated by TIMP. The analysis of serum levels of MMP-3 did not reveal a statistically significant difference between patients with AoV stenosis and the control group. Furthermore, the current study did not identify any significant differences between MMP-9 serum expression levels in patients with AoV stenosis and the control group patients. The above results indicate that the pathophysiological process in AoV stenosis is not the same

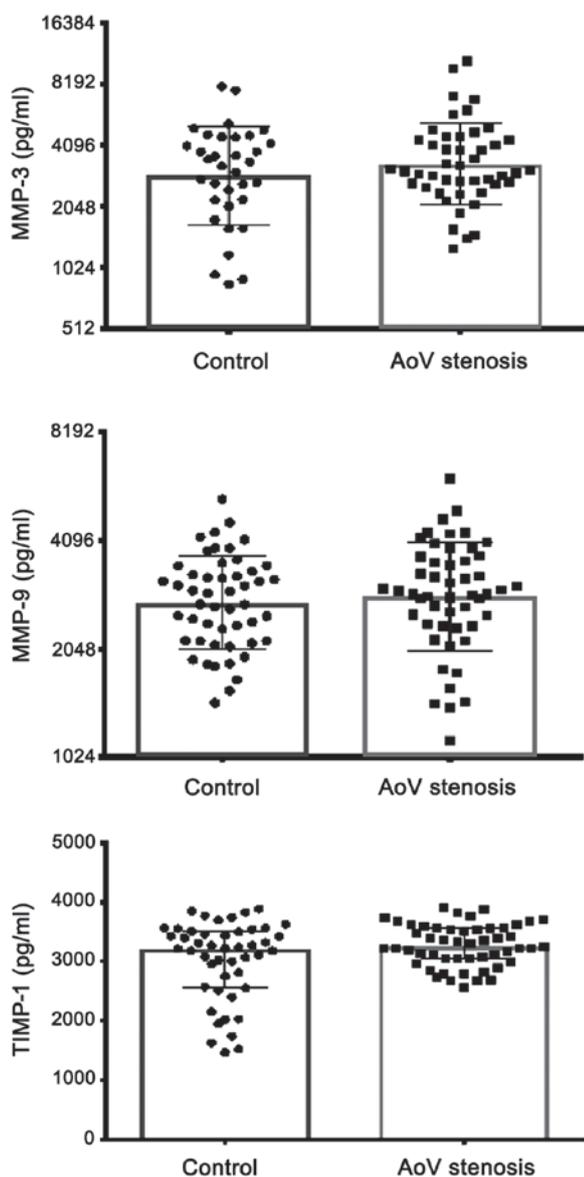

Figure 10. Serum levels of MMP-3, MMP-9, TIMP-1 in the control and AoV stenosis groups. MMP, matrix metalloproteinase; TIMP, tissue inhibitor of metalloproteinase; AoV, aortic valve.

as for atherosclerosis. Papazafropoulou and Tentolouris (15) demonstrated that MMP-9 serves a central role in atherosclerosis, plaque formation, platelet aggregation, acute coronary syndrome, restenosis, aortic aneurysms and peripheral vascular disease. Increased MMP-9 levels are an independent risk factor of cardiovascular mortality among patients with coronary artery disease (16). The current study did not reveal an increase in MMP-9 serum levels in patients with aortic stenosis and did not identify an association between MMP-9 and TIMP-1 serum levels.

Satta *et al* (30) studied the expression of elastolytic MMPs and TIMPs in non-rheumatic aortic stenosis. The study concluded that the disproportion between MMP-9 and its tissue inhibitors may favor persistent MMP activation state within the calcific valve and contribute to the valvular remodeling process in the developing aortic stenosis. Satta *et al* also reported that MMP-9 protein was almost exclusively localized near or around the mineralized nodules, whereas the

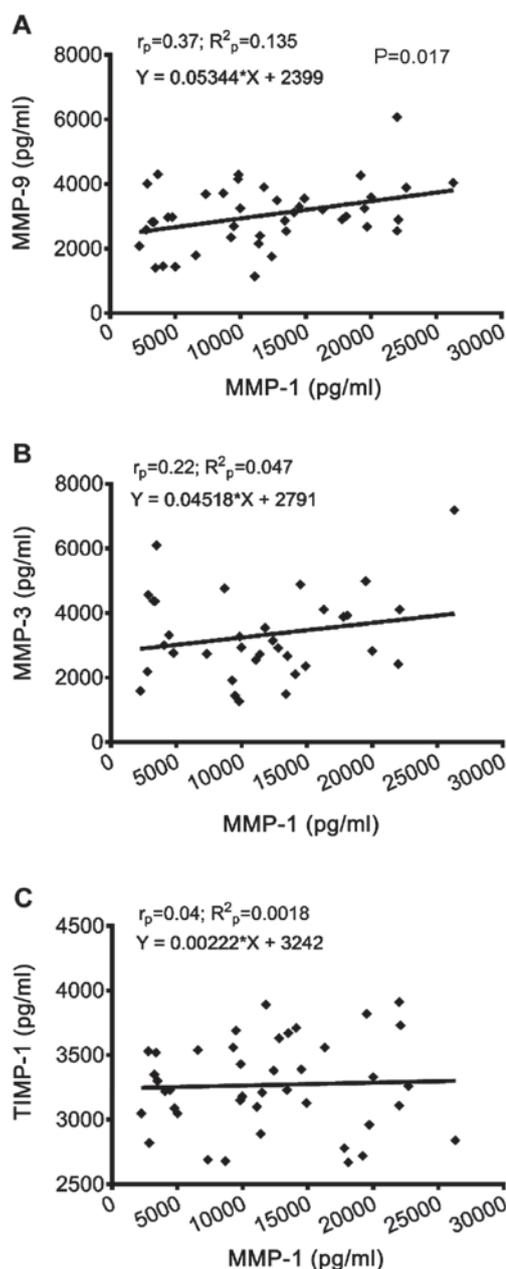

Figure 11. Regression analyses. Regression lines of serum (A) MMP-1 and MMP-9, (B) MMP-1 and MMP-3, and (C) MMP-1 and TIMP-1 in patients with AoV stenosis. AoV, aortic valve; MMP, matrix metalloproteinase.

expression was generally weak or absent in areas devoid of calcification.

The current study did not identify any correlation between the serum levels of TIMP-1 and MMP-9; however, a positive correlation was identified between the serum level of MMP-1 and MMP-9. The results of the current study were compared with those from previous studies involving histological material (15,16,30) and based on these data, it was hypothesized that MMP-9 functions more locally at cellular level. The results of the current study indicated that MMP-1 may serve an important role in patients with aortic valve stenosis. Further studies on the role of MMPs in the development of AoV stenosis could result in clinical application of this knowledge.

The current study further analyzed the association between aortic valve stenosis and inflammatory factors including

chemerin, C-reactive protein and FGF-21. Chemerin has been previously identified in different inflammatory and systemic processes (31,32); and, therefore, patients with systemic and inflammatory diseases were excluded from the current study. Regn *et al* (17) demonstrated that pro-chemerin was expressed and secreted by the cardiac fibroblasts and converted to bioactive chemerin during proteolytic process, substantiating the idea that chemerin may exhibit both, pro- and anti-inflammatory functions. Analyzing the level of chemerin among patients with AoV stenosis and in the control group, the current study demonstrated that the expression chemerin was significantly increased among patients with AoV stenosis. Further analysis of AoV stenosis subgroups revealed that the highest serum chemerin level was present in the mild AoV stenosis group and a progressive decrease of chemerin levels was observed with an increasing degree of stenosis. In the control group the chemerin expression level was significantly lower compared with patients with severe AoV stenosis. Since chemerin is an inflammatory factor (28), its reduction with the progression of aortic stenosis suggests that the inflammation is prevalent at the beginning of the disease; however, calcinosis may predominate at later stages. The C-reactive protein expression results further supported the hypothesis that at the beginning of AoV stenosis the inflammatory prices may be prevalent, as the expression levels of this protein were significantly increased in patients with mild stenosis compared with the control group. Galante *et al* (33) identified and described elevated C-reactive protein levels in degenerative aortic valve stenosis. The aforementioned results suggest that AoV stenosis at early stages may present as an active inflammatory process. At more severe stages, decreased serum chemerin levels suggest that extracellular matrix alterations and calcification may be the dominant processes in moderate and severe calcific AoV stenosis.

Chemerin has been studied as an inflammatory marker and FGF-21 as a factor that could induce a protective effect on the cardiac muscle in case of damage (17,20). FGF-21 has been demonstrated to be released from the rat cardiac endothelial cells *in vitro* (18). FGF-21 was found to improve endothelial function, decrease oxidative stress and prevent endothelial cell apoptosis (18,19,20,21). FGF-21 could serve as a biological marker of stress and damage to endothelial cells and may serve a physiological role in improving endothelial function (18). The expression of FGF-21 was significantly higher in patients with AoV stenosis compared with controls and further increased in patients with severe stenosis. The expression levels of serum chemerin were positively correlated with the levels of FGF-21. These results lead to a hypothesis that FGF-21 may serve a protective role in the pathogenesis of calcific AoV stenosis, as at the initial stages of the disease, only a slight increase in plasma FGF-21 was identified, while a greater increase was identified in patients with severe grade AoV stenosis. Previous studies further suggested that FGF-21 may exhibit a cardio protective role in different cardiovascular diseases including atrial fibrillation, myocardial infarction, coronary artery disease, hypertension, and cardiac hypertrophy (19,20), supporting the results of the current study. FGF-21 also serves a role in the development of connective tissue (21). Considering the multiple effects FGF-21 and the association with connective tissue formation, it may be hypothesized that the increase in FGF-21 expression may be

due to the progression of AoV stenosis and increased connective tissue formation.

The current data indicated that inflammation was dominant at the early, mild stage of AoV stenosis, the most pronounced extracellular matrix remodeling occurred in moderate AoV stenosis and calcification may have been the tominant process in severe calcific AoV stenosis. These results lead to a conclusion that aortic valve stenosis is an active inflammatory process which possibly could be delayed by therapeutic interventions.

To reduce the level of MMPs in patients with aortic valve stenosis, medications (including Nebivolol) that release nitric oxide (NO), could be prescribed, as NO inhibits MMPs production by endothelial cells and smooth muscle cells (15). Oxidized low density lipoprotein cholesterol has been observed to increase and high-density lipoprotein cholesterol to decrease the production of MMP-1 (34). This indicates that treatment of dyslipidemia remains necessary and may protect from the development of a more severe aortic stenosis. Since the elevated level of glucose induces the expression of MMP-1 and MMP-2 from endothelial cells and the expression of MMP-9 from macrophages, it is important to actively treat glucose metabolism disorders in order to ensure maximum possible normoglycemia (35). Based on the results of previous studies investigating the effects of drugs on MMP and TIMP levels, the adverse drugs include nitroglycerin (no long-acting nitrates have been studied, to the best of our knowledge), amlodipine and diltiazem, as well as ACE inhibitors, since angiotensin II decreases MMP-1 activity (36,37). In cardiology, ACE inhibitors are a widely used drug group, and, therefore, the prevalence of progressive aortic stenosis could be partly explained by the wide use of this group of medicines.

Availability of data and materials

The datasets used and/or analyzed during the present study are available from the corresponding author on reasonable request.

Authors' contributions

JL and DL designed the study, analyzed and summarized the literature and were responsible for writing the manuscript. SS analyzed the data. ZK performed the experiments. VM, PT, AL, VR and VB assisted in providing constructive analysis and interpreted the data. All authors read and approve the final manuscript.

Ethics approval and consent to participate

The study protocol was approved by the Riga Stradins University Ethics Committee on Research on Humans (Riga, Latvia) and the study protocol conforms to the Ethical Guidelines of the 1975 Declaration of Helsinki. Written informed consent was obtained from each patient enrolled in the current study.

Patient consent for publication

Written informed consent was obtained from each patient enrolled in the current study.

Competing interests

The authors declare that they have no competing interests.
